Abstract

Durum wheat (*Triticum durum* Desf.) is one of the more widely cultivated crops in the Mediterranean basin, where drought is the main abiotic stress limiting its production. This study was conducted on the experimental site of station ITGC in Setif, Algeria. The objectives of this study were (i) to determine differences in canopy temperature (CT) and canopy temperature depression (CTD) of different durum wheat under both well-watered and moisture stressed conditions and (ii) to correlate canopy temperature (CT) and canopy temperature depression (CTD) with drought resistance indices value and yield of durum wheat (*Triticum durum* Desf.) under both conditions. The results of study showed a significant difference between CT and CTD under both conditions and among
genotypes. Under dryland conditions, grain yield and mean CTD were correlated positively ($r = 0.32^{**}$), this correlation is similar to other studies (Blum et al., 1989; Royo et al., 2002). Similar results of correlation between canopy temperature (CT), canopy temperature depression (CTD) and grain yield suggest that the use of CT and CTD in screening for highly tolerant varieties to drought is similar. The significant correlation of CT and CTD with Mean productivity (MP) and Stress tolerance index (STI) suggests that CTD and/or CT can be favorite selection criteria in plant breeding for drought tolerance.

Keywords: Durum wheat, Canopy temperature, Canopy temperature depression, Drought resistance indices

INTRODUCTION

Wheat production in Mediterranean region is often limited by sub-optimal moisture conditions. Visible syndromes of plant exposure to drought in the vegetative phase are leaf wilting, decrease of plant height, number and area of leaves and delay in accuracy of buds and flowers (Boyer, 1982; Passioura et al., 1993). Durum wheat is grown on 10% of the world wheat area. It occupies approximately 11 million ha in the Mediterranean basin. The world's durum wheat acreage is concentrated in the Middle East, North Africa, Russia, the North American Great Plains, India, and Mediterranean Europe (Golabadi et al., 2006). Water deficit is one of the most important factors limiting crop yield, and the monitoring of crop water status has prime importance for reasonable irrigation and water saving cultivation. Breeding for resistance to drought is complicated by the lack of fast, reproducible screening techniques and the inability to routinely create defined and repeatable water stress conditions where large amount genotypes can be evaluated efficiently (Ramirez and Kelly, 1998). Achieving genetic increase in yield in these environments has been recognized to be difficult challenge for plant breeders while progress in yield grain has been much higher in favorable environments (Richards et al., 2002). Thus, drought indices which provide a measure of drought based on loss of yield under drought condition in comparison to normal conditions have been used for screening drought-tolerant genotypes (Mitra, 2001). These indices are either based on
drought resistance or susceptibility of genotypes (Fernandez, 1992). Canopy temperature measurements have been widely used in recent years to study genotypic response to drought. Blum et al., (1989) used canopy temperatures of drought stresses wheat genotypes to characterize yield stability under various moisture conditions. A positive correlation was found between a drought susceptibility index and canopy temperature in stressed environments. Drought-susceptible genotypes which suffered relatively greater yield loss under stress tended to have warmer canopies at midday. Result from several recent studies show that canopy temperatures under well-watered conditions also provide an indication of potential yield performance during drought and could effectively be used as a technique to assess genotypic response to drought. Rashid et al., (1999) reported that significant correlation between canopy temperature and yield under moisture-stress conditions and stress susceptibility index values indicated the potential for screening wheat genotypes for drought response. Canopy temperature depression, the difference between air temperature (Ta) and canopy temperature (Tc), is positive when the canopy is cooler than the air (CTD = Ta – Tc). It has been used in various practical applications including evaluation of plant response to environmental stress (Ehlerer et al., 1978; Idso, 1982; Howell et al., 1986), irrigation scheduling (Hatfield, 1982), and to evaluate cultivars for water use (Pinter et al., 1990), tolerance to heat (Amani et al., 1996), and drought (Blum et al., 1989; Rashid et al., 1999). In general, CTD has been used to assess plant water status because it represents an overall, integrated physiological response to drought and high temperature (Amani et al., 1996). Overall, the existing literature suggests that dominant mechanisms that increase CTD vary with environment and crop species. CTD effected by biological and environmental factors like water status of soil, wind, evapotranspiration, cloudiness, conduction systems, plant metabolism, air temperature, relative humidity, and continuous radiation (Reynolds et al., 2001), has preferably been measured in high air temperature and low relative humidity because of high vapour pressure deficit conditions (Amani et al., 1996). Therefore, the objectives of this study were (i) to
determine differences in canopy temperature (CT) and canopy temperature depression (CTD) of different durum wheat under both well-watered and moisture stressed conditions and (ii) to correlate canopy temperature (CT) and canopy temperature depression (CTD) with drought resistance indices value and yield of durum wheat (*Triticum durum* Desf.) under both conditions.

**MATERIALS AND METHODS**

Ten durum wheat (*Triticum durum* Desf.) were chosen for study based on their reputed differences in yield performance under irrigated and non-irrigated conditions (Table 1). Experiments were conducted at experimental field of ITGC (Technical Institute of Field Crops) station of Setif, Algeria (5°20'E, 36°8'N, 958 m above mean sea level) during the 2011/2012 cropping year. Genotypes were grown in randomized block design with four replicates. Plots were 2.5 m × 6 rows with 0.20 m row spacing and sowing density was adjusted to 300 g m⁻². All plots of the irrigation experiment were irrigated by using a Sprinklers system and the volume of water input for each plot was controlled. Two irrigation regimes were applied; the first irrigation (15 mm) was performed at the time of heading (50 Zadoks cods), and the second irrigation (25 mm) was applied at grain filling period (70 Zadoks cods). A handheld infrared thermometer (Model TECPEL 513, TAIWAN), with a field of view of 100 mm to 1000 mm, was used to measure CT (°C). The data were taken from the same side of each plot at 1m distance from the edge and approximately 50 cm above the canopy at an angle of 30° to the horizontal. Readings were made between 1300 and 1500 h on sunny days.

At harvest, grain yield were recorded under two conditions irrigated and non irrigated. Drought resistance indices were calculated using the following relationships:

1. Harmonic mean (HM) (Kristin et al., 1997):

   \[
   HM = \frac{2 \times (GY_p \times GY_s)}{(GY_p + GY_s)}
   \]

   GYp and GYs were the yield of each cultivars, non stressed and stressed, respectively.
2. Geometric mean productivity (GMP) and 3. Stress tolerance index (STI) (Fernandez, 1992; Kristin et al., 1997):

\[ \text{GMP} = (\text{GY}_p \times \text{GY}_s)^{\frac{1}{2}} \]

\[ \text{STI} = \frac{(\text{GY}_p \times \text{GY}_s)}{(\text{GY}_p)^2} \]

4. Mean productivity (MP) (Hossain et al., 1990):

\[ \frac{\text{GY}_p + \text{GY}_s}{2} \]

Data were analyzed using SAS for analysis of variance and Fisher’s LSD multiple range test was employed for the mean comparisons.

RESULTS AND DISCUSSION

Grain yield (GY):

The results of the present study indicated that the two different conditions of growth (stressed and non-stressed conditions) had different considerable effects on grain yield. Data concerning grain yield is given in Table 1 and Figure 1, the grain yield of ten genotypes tested ranged between 21.45-36.87 q/ha in stressed condition and 26.62-58.56 q/ha in well-watered condition. Drought resistance is usually quantified by grain yield under drought. Wheat grain yield under drought, however, depends on yield potential as well as the phenology of the genotype (Acevedo, 1991). In this study the difference between grain yield under stressed and non-stressed conditions equal 29.88%. Severe water stress from the seedling stage to maturity reportedly reduced all grain yield components, particularly the number of fertile ears per unit area by 60%, grain number per head by 48% (García del Moral et al., 1991) and grain yield by 12.42% (Guendouz et al., 2012).

Canopy temperature (CT) and Canopy temperature depression (CTD):

Means related with canopy temperature and canopy temperature depression were given in Table 1 and Figure 2, 3. Genotypic variance was significant for CT and CTD under both conditions. The values of canopy temperature (CT) under irrigated condition were ranged between 23.83°C for Sooty to 28°C for Hoggar with an average of 25.99°C over all genotypes, but under stressed condition there is augmentation in the values where ranged from 27°C for Polonicum to 30.66°C for Altar with an average of 28.77°C over all genotypes. The difference between CT under stressed and irrigated conditions equal 10.69%, this
result is in agreement with the finding of Talebi (2011), water stress affect positively canopy temperature. Blum et al., (1989) used canopy temperatures of drought stresses wheat genotypes to characterize yield stability under various moisture conditions. Values of Canopy temperature depression (CTD) ranged between -0.36 for Mexicali to 2.8 for Polonicum with an average of 1.016 over all genotypes in stressed conditions. Under irrigated conditions CTD varied from 1.8 for Hoggar to 5.96 for Sooty with an average of 3.79 over all genotypes tested. Drought stressed plants displayed higher canopy temperatures than well-watered plants (Siddique et al., 2000). High CTD has been used as a selection criterion to improve tolerance to drought and heat (Amani et al., 1996; Ayeneh et al., 2002). The genotypes with negative values of CTD suggest that these genotypes it’s very sensitive to water stress. CTD as a tool for predicting performance (Reynolds et al., 1997). Increase in CTD might have occurred due to increased respiration and decreased transpiration resulting from stomatal closure (Siddique et al., 2000).

**Drought resistance indices (DRIs):**

In this study, the stress intensity (SI) was 27.11 %. It is essential to say that this index is just to measure drought stress intensity in experiment and it has no efficiency to measure stress intensity in varieties (Fisher and Maurer, 1978). Achieved results from calculation of drought tolerance and drought sensitive indices (Table 2) shows that the higher value of MP, GMP and STI indicated stress tolerance. Under both conditions values of GMP, HM and MP ranged between 23-44. The best index to select varieties, is stress tolerance index (STI), as it can separate varieties which has high yield in both stressed and non-stressed conditions (group A) from two groups of varieties which have just relatively better yield under non-stressed (group B) or stressed (group C) conditions (Fernandez, 1992).

**Correlations between CTD, CT and grain yield:**

Under dryland conditions, grain yield and mean CTD were correlated positively ($r = 0.32^{**}$), this correlation is similar to other studies (Blum et al., 1989; Royo et al.,
2002); but under irrigated condition CTD correlated negatively with grain yield \( (r = -0.41^{**}) \) (Table 3). In this study, positive correlation between CTD and grain yield suggests that CTD has been used for selection criteria in breeding programs. Blum (1988) and Balota et al. (2007) proposed CTD as a selection criterion for drought tolerance. Under stressed condition canopy temperature (CT) correlated negatively with grain yield \( (r = -0.32^{**}) \). Similar results were reported by Hirayama et al., (2006) for rice and by Talebi (2011) in Durum wheat. In addition, Fischer et al., (1998) reported that stomatal conductance, photosynthesis and canopy temperature were closely related with yield in spring wheat. The evaluations and line selection of drought tolerance based on the canopy temperature could also be effective in durum wheat to develop highly tolerant varieties to drought (Talebi, 2011). Similar results of correlation between canopy temperature (CT), canopy temperature depression (CTD) and grain yield suggest that the use of CT and CTD in screening for highly tolerant varieties to drought is similar.

**Correlations between CTD, CT and Drought resistance indices:**

Selection for drought tolerance in wheat could be conducted for high MP, GMP and STI under rainfed and supplementary irrigation environments (Golabadi et al., 2006). Selection of different genotypes under environmental stress conditions is one of the main tasks of plant breeders for exploiting the genetic variations to improve the stress-tolerant cultivars (Clarke et al., 1984). Tolerance indices including STI and MP were able to identify cultivars producing high yield under both conditions (Stressed and non stressed conditions) (Shefazadeh et al., 2012). As shown in Table 3, and under both conditions canopy temperature depression (CTD) and Canopy temperature (CT) correlated significantly with Mean productivity (MP) and Stress tolerance index (STI). This significant correlation suggests that CTD and/or CT can be favorite selection criteria in plant breeding for drought tolerance.
CONCLUSIONS
This study showed that the irrigation affect significantly canopy temperature (CT), canopy temperature depression (CTD) and grain yield. Significant correlation between canopy temperature depression, canopy temperature and grain yield suggests that CTD and/or CT has been used for selection criteria in breeding programs. In addition, similar results of the correlation between canopy temperature (CT), canopy temperature depression (CTD) and grain yield suggest that the use of CT or CTD in screening for highly tolerant varieties to drought is identical, and the significant correlation of CT and CTD with Mean productivity (MP) and Stress tolerance index (STI) suggests that CTD and/or CT can be favorite selection criteria in plant breeding for drought tolerance.
